1. Introduction

Martin-Löf’s intensional type theory (MLTT) is the basis of proof assistants such as Agda [29] and Coq [9]. Homotopy type theory is an extension of MLTT based on a correspondence with homotopy theory and higher category theory [4, 11, 13, 14, 24, 36–38].

In homotopy theory, one studies topological spaces by way of their points, paths (between points), homotopies (paths or continuous deformations between paths), homotopy types between homotopies (paths between paths between paths), and so on. In type theory, a space corresponds to a type. Points of a space correspond to elements \( a, b : A \). Paths in a space are represented by elements of the identity type (propositional equality), which we notate \( p : a =_A b \). Homotopies between paths \( p \) and \( q \) correspond to elements of the iterated identity type \( p =_A q \). The rules for the identity type allow one to define the operations on paths that are considered in homotopy theory. These include identity paths \( \text{refl} : a = a \) (reflexivity of equality), inverse paths \( ! p : b = a \) when \( p : a = b \) (symmetry of equality), and composition of paths \( q \circ p : a = c \) when \( p : a = b \) and \( q : b = c \) (transitivity of equality), as well as homotopies relating these operations (for example, \( \text{refl} \circ p = p \)), and homotopies relating those homotopies, etc. This correspondence has suggested several extensions to type theory. One is Voevodsky’s univalence axiom [17, 37], which describes the path structure of the universe (the type of small types). Another is higher inductive types [23, 24, 26], a new class of datatypes specified by constructors not only for points but also for paths. Higher inductive types were originally introduced to permit basic topological spaces such as circles and spheres to be defined in type theory, and have had significant applications in a line of work on using homotopy type theory to give computer-checked proofs in homotopy theory [19, 20, 23, 35].

The computational interpretation of homotopy type theory as a programming language is a subject of active research, though some special cases have been solved, and work in progress is promising [5, 6, 21, 33]. The main lesson of this work is that, in homotopy type theory, proofs of equality have computational content, and can influence how a program runs. This suggests investigating whether there are programming applications of computationally relevant equality proofs. Some preliminary applications have been investigated. For example, Licata and Harper [21] apply ideas related to homotopy type theory to modeling variable binding. Allenkirch [2] shows that containers [1] in homotopy type theory can be used to represent more data structures than in MLTT, such as sets and bags. However, at present, the programming side is less well-developed than the mathematical applications.

In this paper, we present an example of using higher inductive types in programming. The example we consider is patch theory [7, 10, 13, 15, 28, 31], inspired by the version control system Darcs [31]. Intuitively, a patch is a syntactic representation of a function that changes a repository. A patch (“delete file \( f \)”) applies...
in certain repository contexts (where the file \( f \) exists), and results in another repository context (where the file \( f \) no longer exists)—so the contexts act as types for patches. Patches are closed under identity (a no-op), composition (sequencing), and perhaps inverses (undo)—which is present in some formulations of patch theory but not others. These satisfy certain general laws—composition is associative; inverses cancel. Moreover, there are domain-specific patch laws about the basic patches (“the order of edits to independent lines of a file can be swapped”). The semantics of a patch explains how to apply it to change a repository. Several syntactic transformations on patches are considered, such as merging, which reconciles divergent edits to a repository, and cherry-picking, which selects a subset of changes to merge. The semantics and syntactic transformations are required to satisfy certain laws, such as the fact that applying a composition of patches has the same effect as the composition of applying the patches (facilitating optimization), and that merging is a symmetric operation, so that independently computed merges agree (facilitating collaboration).

Building on this work, we develop patch theory in the context of homotopy type theory, using paths to represent aspects of patch theory. Specifically, we represent patches as paths—making use of the proof-relevant notion of equality in homotopy type theory—and we represent the laws that patches and transformations must satisfy as paths-between-paths. We make an explicit distinction between patch theories and models. A patch theory is presented by a higher inductive type, where the points of the type are repository contexts, the paths in the type are patches, and the paths between paths are patch laws. This presentation of a patch theory consists of only the basic patches (“add / remove files”) and laws about them. Identity, inverse, and composition operations are provided by the higher inductive type, and automatically satisfy the desired laws.

Models of a patch theory are represented as functions from the higher inductive type representing it. Because functions in homotopy type theory are always functorial, such models are a functorial semantics in the sense of Lawvere. These models depend crucially on the proof-relevance of paths, assigning proofs of equalities a computational meaning as functions acting on repositories. Functoriality implies that a model must respect identity, inverses, and composition (e.g. sending composition of patches to composition of functions) and validate the patch laws. So a patch theory is a formal object, a particular higher inductive type, and the theory is realized by a formal object, a mapping into another type. One syntactic theory of patches can have many different models, e.g. ones that maintain different metadata. Syntactic transformations on patches, such as patch optimization or merging, can be implemented as functions on paths. Some of these operations can be defined directly in a functorial way, whereas others require developing a derived recursion principle for patches.

Our work shows what standard homotopy-theoretic tools mean in a practical programming setting. For example, our first example of a patch theory is actually the circle. Defining the semantics of patch theories uses a programming technique derived from homotopy-theoretic examples. The derived recursion principle for patches is analogous to calculations of homotopy groups in homotopy type theory. We hope that this paper will make higher inductive types and pattern-matching functions on them; this is similar to the informal type theory used in the Homotopy Type Theory book, but with a more programming-oriented notation. Our development using this syntax could be translated to Agda or Coq, using techniques to simulate higher inductives, but we have not yet implemented the examples in this paper in a proof assistant. Second, because a full interpretation of homotopy type theory as a programming language is work in progress, we do not have a formal operational semantics that we can use to run the programs in this paper. However, we will speculate on how we expect these specific programs to run, based on existing work on this topic. One interesting issue that arises is that several of the examples in the paper are functions into contractible types, which are types with exactly one inhabitant up to homotopy. Thus, up to paths/propositional equality, such a function can return any element of the type, but based on existing work on the computational interpretation, we expect that the functions we define will in fact compute the elements we intend them to.

In Section we provide a brief introduction to homotopy type theory and higher inductive types. In Section we review patch theory, and describe our approach to representing it in homotopy type theory. In Sections and we discuss three successively more complex patch languages.

2. Basics of Homotopy Type Theory

We review some basic definitions; see for more details.

2.1 Paths

In type theory, there are two notions of equality. Definitional equality is a proof-irrelevant judgement relating two terms. It is a congruence containing operational steps like \( \beta \)-reduction (\( \lambda x.e \) = \( e' \)) is definitionally equal to \( [e/ x] e' \). Uses of definitional equality are not marked in the proof term or program: if \( e \) has type \( \tau \), then \( e \) also has any other type \( \tau^0 \) that is definitionally equal to \( \tau \). On the other hand, propositional equality is a proof-relevant type relating two terms; it is often also called the identity type, which we write \( e = e' \). Uses of propositional equality are explicitly marked in the program: if \( e \) has type \( \tau \) and \( p \) is an element of the identity type \( \tau = \tau^0 \), then \( \text{coe} \ p \ e \) has type \( \tau^0 \).

In homotopy type theory, elements of the identity type are used to model a notion of paths in a space or morphisms in a groupoid. Using the identity type, specified by its introduction rule, reflexivity, and elimination rule, known as path induction or \( J \), one can define path operations including a constant path \( \text{refl} \) (witnessing the reflexivity of equality); composition of paths \( q \circ p \) (witnessing the transitivity of equality) and the inverse of a path \( p \) (witnessing the symmetry of equality). Moreover, there are paths between paths, or homotopies, which are represented by proofs of equality in identity types. For example, there are homotopies expressing that the path operations satisfy the group(oid) laws:

\[
\text{refl} \circ p = p = p \circ \text{refl} \quad (r \circ q) \circ p = r \circ (q \circ p) \quad ((p \circ q) \circ r = (p \circ (q \circ r))
\]

Any simply-typed function \( f : A \to B \) determines a function

\[
\text{ap} \ f : x = y \to f(x) = f(y)
\]

that takes paths \( x \to A \) to paths \( f(x) \to f(A) \). Logically, this expresses that propositional equality is a congruence; homotopically, it expresses that any function has an action on paths; and categorically, it expresses that functions are functors, preserving the path

\[\text{coe} p e = \tau \]

There is an unfortunate terminological coincidence here: “Patch theory” means “the study of patches,” just as “group theory” is the study of groups. “A patch theory” means “a specific language of patches,” just as “a theory in first-order logic” is a specific collection of terms and formulae.

Composition is in function-composition, or applicative, order, \( (q : y = z) \circ (p : x = y) = x = z \).
structure of types. \( \text{ap} \ f \) preserves the path operations, in the sense that there are homotopies
\[
\begin{align*}
ap f (\text{refl}(x)) &= \text{refl}(f x) \\
ap f (! p) &= ! (\text{ap} f p) \\
ap f (q \circ p) &= (\text{ap} f q) \circ (\text{ap} f p)
\end{align*}
\]
For a family of types \( B : A \rightarrow \text{Type} \) and a dependent function \( f : (x : A) \rightarrow B(x) \), there is a function
\[
\text{apd} : (p : x = y) \rightarrow \text{PathOver} B p (f x) (f y)
\]
PathOver \( B \) \( p \) \( b1 \) \( b2 \) represents a path in the dependent type \( B \) between \( b1 : B(a1) \) and \( b2 : B(a2) \) correlated by a path \( p : a1 = a2 \). Logically, it is a kind of heterogeneous equality \(^{[27]}\); categorically, it is a path in the total space of the fibration determined by the type family. For \( \text{apd} \), this kind of heterogeneous equality is necessary because \( f x : B(x) \) whereas \( f y : B(y) \).

2.2 \( n \)-types
A type \( A \) is a set, or 0-type, iff any two parallel paths in \( A \) are equal—for any two elements \( m,n : A \) and any two proofs \( p,q : m = n \), there is a path \( p = q \). Similarly, a type is a 1-type iff any two paths between parallel paths are equal. A type is a mere proposition, or \((-1)\)-type, iff any two elements are equal. A type is contractible iff it is a mere proposition and moreover it has an element.

2.3 Univalence
Writing Type for a type of (small) types, Voevodsky’s univalence axiom states that, for sets \( A \) and \( B \), the paths \( A =_{\text{Type}} B \) are given by bijections between \( A \) and \( B \)
That is, define \( \text{Bijection} \ A \ B \) to be the type of quadruples
\[
\begin{align*}
f : A &\rightarrow B, \\
g : B &\rightarrow A, \\
p : (x : A) &\rightarrow g(f x) = x, \\
q : (y : B) &\rightarrow f(g y) = y
\end{align*}
\]
consisting of two functions that are mutually inverse up to paths. Then one consequence of univalence is that there is a function
\[
\text{ua} : \text{Bijection} \ A \ B \rightarrow A = B
\]
which says that a bijection between \( A \) and \( B \) determines a path between \( A \) and \( B \). The force of this is to stipulate that all constructions respect bijection; for example, if \( C[X] \) is a parametrized type (e.g. \( C \) could be \( \text{List} \), \( \text{Tree} \), \( \text{Monoid} \), etc.), then a given bijection \( b : \text{Bijection} \ A \ B \), we have
\[
\text{ap} C (\text{ua} b) : C[A] = C[B]
\]
which is a bijection between \( C[A] \) and \( C[B] \). In plain MLTT, one would need to spell out how a bijection between types lifts to a bijection on lists or monoids over those types; with univalence, this lifting is given by a new generic program in the form of \( \text{ap} \). This generic program is one of the sources of computational applications of homotopy type theory.

We can define the identity, inverse, and composition of bijections directly (focusing on the underlying functions, and writing \( f1 \) \( \cdot \) \( f2 \). \( f 1 \) for \( (\lambda x \rightarrow f2(f1(x))) \)):
\[
\begin{align*}
\text{refl} b &= \text{Bijection} \ A \ A \\
\text{refl} b &= ((\lambda x \rightarrow x), (\lambda x \rightarrow x), \ldots)
\end{align*}
\]
\( 1b : \text{Bijection} \ A \ B \rightarrow \text{Bijection} \ B \ A \\
1b (f,g,p,q) &= (g,f,q,p)
\]
\( \text{ob}_b : \text{Bijection} \ C \rightarrow \text{Bijection} \ A \ B \rightarrow \text{Bijection} \ A \ C \)
\( (f2,g2,p2,q2) \ \text{ob} (f1,g1,p1,q1) = (f2 \cdot f1, g1 \cdot g2, \ldots) \)
Applying path operations to univalence is homotopic to applying the corresponding operations to bijections:

For types that are not sets, univalence requires a notion of equivalence that generalizes bijection. However, here we will only use it for sets.

\[
\begin{align*}
\text{ua} \ \text{refl} b &= \text{refl} 1 \ \text{ua} b &= \text{ua} 1b b \\
\text{ua} b2 \circ \text{ua} b1 &= \text{ua} (b2 \circ b1 b)
\end{align*}
\]
When \( p : A = B \), we write \( \text{coe} p : A \rightarrow B \) for the function, defined by identity type elimination, that “coerces” along the path \( p \). \( \text{coe} \) is functorial, in the sense that
\[
\begin{align*}
\text{coe} \ \text{refl} x &= x \\
\text{coe} (q \circ p) &= \text{coe} q \circ \text{coe} (q \circ p)
\end{align*}
\]
\( \text{coe} p \) is a bijection, with inverse \( \text{coe} 1p \); we write \( \text{coe}-\text{bijection} \ p : \text{Bijection} A B \) when \( p : A = B \). The univalence axiom additionally asserts that there is a computation rule
\[
\text{coe} (\text{ua} (f,g,p,q)) = f(x)
\]
That is, coercing along a path constructed by univalence applies the given bijection. Because \( \text{ua} (f,g,p,q) = \text{ua} 1b (f,g,p,q) \), we also have that
\[
\text{coe} (\text{ua} (f,g,p,q)) = x = g x
\]
Because of these rules, in the presence of univalence, paths can have non-trivial computational content. A bijection \( (f,g,p,q) \) determines a path \( \text{ua}(f,g,p,q) \), and coercing along this path applies \( f \). Thus, two different bijections \( (f,g,p,q) \) and \( (f',g',p',q') \) determine two paths \( \text{ua}(f,...) \) and \( \text{ua}(f',...,\) that behave differently when coerced along.

2.4 Higher Inductive Types
Ordinary inductive types are specified by generators; for example, the natural numbers have generators zero and successor \( : \text{Nat} \rightarrow \text{Nat} \). Higher-dimensional inductive types (or just higher inductive types) \(^{[25][26][22]}\) generalize inductive types by allowing generators not only for points (terms), but also for paths. For examples, one might draw the circle like this:

This drawing has a single point, and a single non-identity loop from this base point to itself. This translates to a higher inductive type with two generators:

\[
\begin{align*}
\text{space} \text{Circle} : \text{Type where} \\
&\text{-- point constructor:} \\
&\text{base} : \text{Circle} \\
&\text{-- path constructor:} \\
&\text{loop} : \text{base} = \text{base}
\end{align*}
\]

\text{base} constructs an element of the inductive type (taking no arguments, just like \( \text{zero} : \text{Nat} \)). \text{loop} generates a path on the circle, which is an element of the identity type \( \text{base} =_{\text{Circle base}} \) think of this as “going around the circle once clockwise”. The paths of higher inductive types are constructed from generators, such as \text{loop}, using the path operations described above. The intuition is that \text{refl} stands still at the base point, whereas \text{loop} \circ \text{loop} goes around the circle twice clockwise, and \text{loop} goes around the circle once counter-clockwise.

2.4.1 Circle Recursion
The fact that the type of natural numbers is inductively generated by zero and successor is encoded in its elimination rule, primitive recursion. Primitive recursion says that to define a function \( f : \text{Nat} \rightarrow \text{X} \), it suffices to map the generators into \( X \), giving \( x0 : X \) and \( x1 : X \rightarrow X \). Then the function \( f \) satisfies the equations
\[
\begin{align*}
f \text{zero} &= x0 \\
f (\text{succ} n) &= x1(f n)
\end{align*}
\]

^{[27]} For types that are not sets, univalence requires a notion of equivalence that generalizes bijection. However, here we will only use it for sets.
Similarly, the circle is inductively generated by base and loop, so to define a function from the circle into some other type, it suffices to map these generators into that type, which means giving a point and a loop in that type. That is, to define a function \( f : \text{Circle} \to X \), it suffices to give \( b' : X \) and \( l' : b' \circ l' \).

For an inductive type, the \( \beta \)-reduction rules state that applying the elimination rule to a generator computes to the corresponding branch. Thus, by analogy, the computation rules for the circle should say that, for a function \( f : \text{Circle} \to X \) that is defined by giving \( b' \) and \( l' \),

\[
\begin{align*}
  f \text{ base} & = b' \\
  f \text{ loop} & = l' - \text{ does not typecheck!}
\end{align*}
\]

The second equation does not quite make sense, because \( f \) is a function \( \text{Circle} \to X \) but \( \text{loop} \) is a \text{path} on the circle. Therefore we use \( \text{ap} \) (defined above) to denote \( f \)’s action on paths:

\[
\text{ap } f \text{ loop} = l'
\]

This computation rule preserves types because its left-hand side is a proof of \( f \text{ base} = f \text{ base}, \) which by the first computation rule equals \( b' = b' \), which is the type of \( l' \).

**Example 2.1.** As a first example, we write a function to “reverse” a path on the circle—to send the path that goes around the circle \( n \) times clockwise to the path that goes around the circle \( n \) times counter-clockwise, and vice versa. Because a path on the circle is represented by the identity type \( \text{base} = \text{base} \), we seek a function

\[
\begin{align*}
  \text{revPath} : (\text{base} = \text{base}) & \to (\text{base} = \text{base})
\end{align*}
\]

such that, for example, \( \text{revPath} \text{ (loop o loop)} = ! \text{ loop o} \text{ ! loop and revPath} (! \text{ loop o } ! \text{ loop}) = \text{loop o loop} \).

We could define this function by \( \text{revPath} p = ! p \), but because the goal is to illustrate circle recursion, we instead give an equivalent definition that analyzes \( p \).

To define this function using circle recursion, we need to rephrase the problem as constructing a function \( \text{Circle} \to X \) for some type \( X \). The key idea is to define a function \( \text{rev} : \text{Circle} \to \text{Circle} \) and then define \( \text{revPath} \) to be \( \text{ap rev} \). That is, to define a function on the paths of the circle, we define a function on the circle itself, whose action on paths is the desired function. In this case, we define

\[
\begin{align*}
  \text{rev} : \text{Circle} & \to \text{Circle} \\
  \text{ap rev base} & = \text{base} \\
  \text{ap rev loop} & = ! \text{ loop} \\
  \text{revPath p} & = \text{ap rev p}
\end{align*}
\]

One technical issue about higher inductive types is whether the computation rule \( \text{ap } f \text{ loop} = l' \) is a definitional equality or a path/propositional equality. Current models and implementations justify only the latter, so we will take it to be a propositional equality. When we illustrate how programs run in this paper, we will do it by giving a sequence of propositional equalities relating a program to a value, so the rule still functions as a “computation” step—as do the rules mentioned above, which state that \( \text{ap} \) behaves homomorphically on paths built from the group operations. For example, one can calculate

\[
\begin{align*}
\text{revPath} \text{ (loop o loop)} &= \text{ap rev (loop o loop)} \\
&= (\text{ap rev loop}) \circ (\text{ap rev loop}) \\
&= ! \text{ loop o } ! \text{ loop}
\end{align*}
\]

Just as the recursion principle for the natural numbers can be generalized to an induction principle, the full form of the circle elimination rule is a principle of “circle induction”: to define a dependent function \( f : (x : \text{Circle}) \to C(x) \), it suffices to give \( b' : C(\text{base}) \) and \( l' : \text{PathOver C loop b' b'} \).

3. **General Patch Theory**

**Patch theory [7,10,12,15,16,28]** provides a general framework for describing properties of version control systems, which allows us to specify the behavior of patches under operations such as composing, reverting and merging. Here, we formulate patch theory in the context of homotopy type theory. This allows us to separate the purely algebraic aspects of a version control system (the laws that it must obey) from its implementation details (how repositories and patches are represented). We refer to a particular algebraic characterization of a version control system as a theory of version control, or a patch theory; and to an implementation that obeys the laws of such a theory as a model of that theory.

In a patch theory, each patch comes equipped with specified domain and codomain contexts, representing respectively, the repository states on which a patch is applicable, and the states resulting from such an application. For example, a patch that deletes a file is applicable only to states in which the file exists, and results in a state in which it does not. In addition, patches respect certain laws that relate sequences of patches to equivalent sequences of patches—equivalent, in the sense that the two sequences have the same effect on the state of a repository.

### 3.1 Patch Theories as Higher Inductive Types

Homotopy type theory allows us to present a patch theory as a higher inductive type whose structure encodes both generic aspects of version control (such as the behavior of patches under composition) as well as the aspects particular to the given theory, specifying the basic patches available and the specialized laws that these patches obey. An advantage of this approach is that in homotopy type theory functions are functors that necessarily preserve the path structure of a type, so that any function we define out of the higher inductive type representing a patch theory must validate all the laws of that theory, and thus determines a model for it. An additional benefit of this approach is that the metatheory of homotopy type theory itself enforces the groupoid laws, so that we need not specify the behavior of patches and patch laws under composition—i.e. that all compositions are associative, unital and respect inverses—this all comes for free from the groupoid structure of higher inductive types. In the following sections we will present several examples of patch theories encoded as higher inductive types, together with interpretations for them as functors to a universe of sets.

When encoding a patch theory as a higher inductive type, patch contexts are represented as points of the type. Patches are represented as paths between the representations of their domain and codomain contexts, with the path operations \( r e f l \), \( q \circ p \) and \( ! p \) representing a no-op patch, patch composition, and undo, respectively. Encoding patches as paths in a higher inductive type imposes the requirement that they have inverses, as opposed to just retractions. As one would expect, applying the inverse of a patch after applying the patch itself \((! p \circ p)\) undoes the effect of the patch. But it is also possible to apply the inverse patch first \((p \circ ! p)\), to an appropriate repository state, and this composition should also be equivalent to doing nothing. This forces us to use some care when defining contexts and patches. In some cases we use inverse patches directly in our theory, while in others they end up getting in the way and we must work around them.

Patch laws are represented as 2-dimensional paths between paths. Patch laws are helpful for reasoning about syntactic transformations on patches, such as an optimizer, which should compute a patch equivalent to the one it is given, or a merge, which, given two divergent edits, computes a pair of patches that reconciles them.
3.2 Merging

At a minimum, merging is an operation that takes a pair of diverging patches or span, \((f_1, f_2)\), and returns a pair of converging patches or cospan, \((g_1, g_2)\), which is a reconciliation of the span in the sense that

\[
merge(f_1, f_2) = (g_1, g_2) \implies g_1 \circ f_1 = g_2 \circ f_2
\]

In order to support distributed version control systems, we will further require that the merge operation be symmetric,

\[
merge(f_1, f_2) = (g_1, g_2) \implies merge(f_2, f_1) = (g_2, g_1)
\]

so that your reconciliation of my changes with your changes agrees with my reconciliation of your changes with my changes.

Depending on the circumstances, we may wish to impose other laws on merge as well. For example, in the patch theory underlying the distributed revision control system Darcs\[12, 31\], the merge operation is required to respect patch inverses in the sense that,

\[
merge(f_1, f_2) = (g_1, g_2) \implies merge(f_1, f_1) = (g_1, g_2)
\]

A symmetric reconciliation with this property is equivalent to—indeed, the categorical mate of—an operation known as pseudo-commutation, which is the primitive operation in terms of which the other operations of Darcs’ patch theory are defined.

It is always possible to define a total merge function, since for any span we may give \(merge(f_1, f_2) = ([f_1, f_2])\), the reconciliation that undoes both changes. This can be used to signal a merge conflict, a situation in which we are unable to automatically reconcile the competing changes in a sensible way, and for which human intervention is required.

It is important to realize that a merge function that is a symmetric reconciliation need not respect the groupoid structure of a higher inductive type. For example, we may define merge recursively by tiling, that is, define

\[
merge(g \circ f, h) = (h'', g' \circ f')
\]

where

\[
(h'', f'') = merge(f, h),
\]

\[
(h'', g') = merge(g, h')
\]

If we define merging a patch with a no-op and merging a patch with itself by

\[
merge(f, refl) = (refl, f)
\]

\[
merge(f, f) = (refl, refl)
\]

then under the assumption that \(f\) conflicts with \(h\), merging \((f \circ f, h)\) by tiling results in a conflict, whereas first performing the composition yields \((h, refl)\).

Nevertheless, we may still define merge recursively by quotienting syntactic paths by the groupoid and domain-specific patch laws, and choosing a canonical representative for each class. For example, in a theory without any domain-specific laws, we may normalize \(z \circ (refl \circ y) \circ ((x \circ t) \circ w)\) to \(z \circ y \circ x\) with a canonical association. In the presence of domain-specific laws, these would need to be taken into account as well. We will make use of this technique in section 4.

Next, we present several examples of patch theories as higher inductive types. We show how to implement their semantics, and additionally some examples of patch optimization and merging, to illustrate syntactic transformations.

4. An Elementary Patch Theory

First, we define a very simple language of patches, to illustrate the basic technique: we take the repository to be a single integer, and the patches to be adding or subtracting some number \(n\) from it. Because all patches apply to any repository state, we need only a single patch context, which we call \(num\). Patches will then be represented as paths \(num = num\), which represents the fact that every patch can be applied to context \(num\) and results in context \(num\). Suppose we have a patch \(add1\) that represents adding 1 to the repository. Then, because paths can be constructed from identity, inverses, and composition, we also have paths \(refl\), which represents adding 0, and \(add1 \circ add1\), which represents adding 2, and \(! add1\), which represents subtracting 1, and so on. In fact, the patches adding \(n\) for any integer \(n\) are generated by \(add1\), because the integers are the free group on one generator. This motivates the following higher inductive definition of this simple Repository and its patches:

\[
\text{space } R : \text{Type where}
\]

- point constructor (patch context):
  \(num : R\)
- path constructor (basic patch):
  \(add1 : num = num\)

This is, of course, just a renaming of the circle!

\textbf{Remark 4.1.} By presenting it using a higher inductive type, the patch theory automatically includes identity, inverses, and composition. Without higher inductive types, one would need syntax constructors for identity, composition, and inverses; e.g. using a datatype as follows:

```plaintext
data Patch where
add1 : Patch
id : Patch
compose : Patch → Patch → Patch
inv : Patch → Patch
```

Then, to achieve the correct equational theory of patches, one would need to impose the group laws on this type; this could be done using a quotient type\[\text{5}\] to assert that

\[
\text{assoc : compose r (compose q p) = compose (compose r q) p}
\]

\[
\text{inver : compose p (compose p) = id}
\]

\[
\text{unitr : compose p id = p}
\]

\[
\text{unitl : compose id p = p}
\]

By representing a patch theory as a higher inductive type, the group operations and laws are provided by the ambient type theory, so the definition need not include these boilerplate constructors.

\textbf{4.1 Interpreter}

Next, we define an interpreter, which explains how to apply a patch to a repository. Because the intended semantics is that the repository is an integer, we would like to interpret the repository context \(num\) as the type \(\text{Int}\) of integers. Because patches are invertible, we would like to interpret each patch as an element of the type \(\text{Bijection Int Int}\).
Remark 4.2. To build intuition, consider writing the interpreter "by hand", for the quotient type Patch defined in Remark 4.1, which includes constructors for identity, inverse, and composition. We would first define:

```haskell
interp : Patch → Bijection Int Int
interp add1 = successor
interp id = reflb
interp (compose p1 p2) = interp p2 o interp p1
interp (inv p) = !b (interp p)
```

where successor : Bijection Int Int is the bijection given by \( (\lambda x . x + 1, \lambda x . x - 1, \ldots) \) Then, to show that this definition is well-defined on the quotient of patches by the group laws, we would need to do a proof with 5 cases for the 5 group laws, where in each case we appeal to the inductive hypotheses and the corresponding group law for bijections.

Returning to our higher-inductive representation of patches, we define the interpreter using the recursion principle for \( R \), which is of course the same as circle recursion, as discussed in Section 2. We want to interpret each point of \( R \), which represents a repository context, as the type of repositories in that context, and each path as a bijection between the corresponding types. In this case, that means we would like to interpret \( \text{num} \) as \( \text{Int} \) and \( \text{add1} \) as the successor bijection. \( R \)-recursion says that to define a function \( f : R \rightarrow X \), it suffices to find a point \( x_0 : X \) and a loop \( p : x_0 = x_0 \). Thus, we can represent the interpretation by a function \( R \rightarrow Type \), because a point of \( Type \) is a type, and a loop in \( Type \) is, by univalence, the same as a bijection! This motivates the following definition:

\[
I : R \rightarrow Type
I \text{ num} = \text{Int}
\]

Using the computation rules for \( \text{ap} \), we can calculate that \( \text{interp} \) \text{add1} = \text{successor},

\[
\text{interp add1} = \text{coe-biject} (\text{ap I add1}) \quad \text{[definition]}
\]

\[
\text{interp add1} = \text{successor}
\]

using the computation rules for \( \text{ap} \) on \( \text{add} \) (from higher inductive elimination) and \( \text{coe} \) on \( \text{ua} \) \( b \) (from univalence).

Moreover, \( \text{interp} \) takes path operations to the corresponding operations on bijections, because it is defined via \( \text{ap} \) and \( \text{ap} \) preserves the path operations. For example,

\[
\text{interp} (q \circ p) = \text{coe-biject} (\text{ap I (q \circ p)}) \quad \text{[ap on o]}
\]

\[
\text{interp} (q \circ \text{interp} p) = \text{coe-biject} (\text{ap I p}) \quad \text{[coe on ua successor]}
\]

\[
\text{interp} q \circ \text{interp} p = \text{interp} (q \circ p)
\]

\[
\text{interp refl} = \text{reflb} \quad \text{[refl on o]}
\]

\[
\text{interp} (\text{interp} p) = !b (\text{interp} b)
\]

are similar. That is, the semantics is functorial. We elide the projection from \( \text{Bijection A B} \rightarrow \text{A} - \text{B} \).

Comparing this definition of \( \text{interp} \) with Remark 4.2, we see that the recursion principle for the higher-inductive representation of patches provides an elegant way to express the semantics of a patch theory, where much of the code in Remark 4.2 is provided "for free". We needed to give only the key case for \( \text{add1} \), and not the inductive cases for the group operations—the semantics of the basic patches is automatically lifted functorially to the patch operations. Moreover, we did not need to prove that bijections satisfy the group laws—this fact is necessary for the univalence axiom to make sense, so it is effectively part of the metatheory of homotopy type theory, rather than of our program. This example illustrates that univalence can be used to extract computational content from a path, by mapping the path into a path in the universe, which by univalence can be given by a bijection.

Because \( R \) is the circle, one may wonder about the topological meaning of this interpreter. In fact, the type \( \text{I} \) defined here is called the universal cover of the circle, and is discussed further in [23, 35]. \( \text{interp} \) computes what is called the winding number of a path on the circle, which can be thought of as a normal form that counts how many times that path goes around the circle, after "detours" such as loop \( \circ \) loop have been reduced.

It is also worth noting that, although we were thinking of \( \text{num} \) as an integer and \( \text{add1} \) as successor, there is nothing forcing this interpretation of the syntax: we can give a sound interpretation \( I \) in any type with a bijection on it. For example,

\[
I' : R \rightarrow Type
I' \text{ num} = \text{Bool}
\]

In the next section we show how to augment a patch theory with equations such as these—but doing so would of course rule out the previous semantics in \( \text{Int} \), because adding \( I \) to an integer is not self-inverse. The equational theory of \( R \) is complete for the interpretation as \( \text{Int} \), which in homotopy theory is known as the fact that the fundamental group of the circle is \( \mathbb{Z} \) (see [23, 35]). The idea that we can have multiple models of a patch theory (\( I \) and \( I' \)) will be exploited in Section 6 when we give a "logging" interpretation that produces a data representation of what happens when a patch is evaluated.

### 4.2 Merge

Next we implement a merge operation, which satisfies the laws discussed in Section 3. Writing Patch for doc = doc, and specializing the interface to the setting where we have only one context, we need to implement the following:

\[
\text{merge : Patch \times Patch \rightarrow Patch \times Patch}
\]

\[
\text{reconcile} : (f1 f2 g1 g2 : Patch)
\]

\[
\rightarrow \text{merge} (f1 , f2) = (g1 , g2)
\]

\[
\text{symmetric} : (f1 f2 g1 g2 : Patch)
\]

\[
\rightarrow \text{merge} (f1 , f2) = (g1 , g2)
\]

In this simple setting, any two patches commute, essentially because addition is commutative. Thus, we define

\[
\text{merge} (f1 , f2) = (f2 , f1)
\]
For symmetric, because $g_1 = f_2$ and $g_2 = f_1$, we need to show that $\text{merge} (f_2,f_1) = (f_1,f_2)$, which is true by definition.

For reconcile, we need to prove that $f_2 \circ f_1 = f_1 \circ f_2$, for any two loops $f_1$ and $f_2$. This is true because homotopy type theory does not provide a direct induction principle for the loops in a type. That is, there is no built-in elimination rule that allows one to, for example, analyze a loop $f$ as either $\text{add1}$, or the identity, or an inverse, or a composition—because such a case analysis would additionally need to respect all equations on paths, which differ from type to type. Instead, such induction principles for paths are proved for each type from the basic induction principles for the higher inductive types—roughly analogously to how, for the natural numbers, course-of-values (or strong) induction is derived from mathematical induction. Moreover, proving these induction principles is sometimes a significant mathematical theorem. In homotopy theory, it is called calculating the homotopy groups of a space, and even for spaces as simple as the spheres some homotopy groups are unknown. However, we have developed some techniques for calculating homotopy groups in type theory [19,20,23,35], which can be applied here.

For this particular example, the calculation has already be done: we know that the fundamental group of the circle is $\mathbb{Z}$. Specifically, we know that the type $\text{num} = \text{num}$ of loops at $\text{num}$, which we use to represent patches, is in bijection with $\text{Int}$. That is, the integers give canonical representatives (“$add x$, for $x \in \mathbb{Z}$”) for equivalence classes of paths in the above path theory, considered modulo the group laws. This is proved by giving functions back and forth that compose to the identity. The function $\text{encode} : \text{num} = \text{num} \to \text{Int}$ is exactly $\lambda p \to \text{interp} p 0$, for $\text{interp}$ as defined above. The function $\text{repeat} : \text{Int} \to \text{num} = \text{num}$ is defined by induction on the $\text{Int}$, viewing $\text{Int}$ as a datatype with three constructors, $0$, $\times n$ (where $n$ itself is positive) representing positive $n$; and $- n$ (where $n$ itself is positive) representing negative $n$.

\[
\begin{align*}
\text{repeat } 0 &= \text{refl} \\
\text{repeat } (+ n) &= \text{add1} \circ \text{add1} \circ \ldots \circ \text{add1} \ [n \text{ times}] \\
\text{repeat } (- n) &= \text{add1} \circ \text{add1} \circ \ldots \circ \text{add1} \ [n \text{ times}]
\end{align*}
\]

The proof that $\text{encode}$ and $\text{repeat}$ are mutually inverse is described in [23,35]. Moreover, they define a group homomorphism, which means that $\text{repeat}(x+y) = \text{repeat } x \circ \text{repeat } y$.

The bijection between $\text{num} = \text{num}$ and $\text{Int}$ induces a derived induction principle, which says that to prove $P(p)$ for all paths $p : \text{num} = \text{num}$, it suffices to prove $P(\text{repeat } n)$ for all integers $n$. Any path can be viewed as $\text{repeat } n$ for some $n$. Applying this (twice) to the goal $f_2 \circ f_1 = f_1 \circ f_2$, it suffices to show $\text{repeat } x \circ \text{repeat } y = \text{repeat } y \circ \text{repeat } x$.

This is proved as follows:

\[
\begin{align*}
\text{repeat } x \circ \text{repeat } y &= \text{repeat } (x+y) \ [\text{group homomorphism}] \\
&= \text{repeat } (y+x) \ [\text{commutativity of addition}] \\
&= \text{repeat } y \circ \text{repeat } x
\end{align*}
\]

Thus, for this language of patches, the correctness of merge follows from the fact that the fundamental group of the circle is $\mathbb{Z}$—our first example of a software correctness proof being a corollary of a theorem in homotopy theory!

One further point to note is that, in this example, we were able to define merge without converting paths to integers, while to prove the reconciliation property we needed to reason inductively, using canonical representatives of group-law-equivalence-classes. This is because all patches commute, so we can define $\text{merge}(x,y) = (y,x)$ without analyzing the structure of patches. In more interesting settings, such as Section 6, we will need to make use of such representatives to define the merge function itself. To illustrate this, we give an alternate definition of merge, called $\text{merge}'$, which uses a helper function $\text{mergeI}$ that recursively swaps two integers; writing the code in this way illustrates a method for defining merge by choosing canonical representatives for paths and then analyzing these representatives.

\[
\begin{align*}
\text{merge}'(p,q) &= \text{let } (a,b) = \text{mergeI } (p, \text{encode } q) \text{ in } (\text{repeat } a, \text{repeat } b) \\
\text{mergeI} : \text{Int} \times \text{Int} &\to \text{Int} \\
\text{mergeI}(x,y) &= \text{let } (a,b) = \text{mergeI}(x+y) \text{ in } (a-1, b+1)
\end{align*}
\]

The function $\text{merge}'$ is defined by converting the given paths $p$ and $q$ (which are considered up to the group laws, such as associativity) to chosen representatives, integers. Paths that are equal according to the group laws are sent to equal representatives; e.g. both $(\text{add1} \circ \text{add1}) \circ \text{add1}$ and $\text{add1} \circ (\text{add1} \circ \text{add1})$ are sent to $3$. We may then compose this choice of representatives with any function we want — including functions that do not themselves respect the group laws, as merge in general might not (see Section 3) — and the overall composite still respects the group laws. In this case, we compose with a function $\text{mergeI}$ that case-analyzes the given integers, and recursively “merges” the two numbers with cases such as the one given above. This case copies a positive successor on the left to a positive successor on the right, and a negative successor on the right to a negative successor on the left—think of it as merging “add 1 and then do x” with “subtract 1 and then do y” by merging $x$ and $y$ and then moving the “add 1” to the right and the “subtract 1” to the left. Finally, once $\text{mergeI}$ has computed the merge of two chosen representatives, $\text{merge}'$ calls $\text{repeat}$ to convert the resulting integers back to paths. One can prove by induction that $\text{mergeI}(x,y) = (x,y)$; and $\text{encode}$ and $\text{repeat}$ are mutually inverse, so $\text{merge}'$ agrees with the original definition of merge.

5. A Patch Theory with Laws

In this section, we consider a slightly more complex patch theory, to illustrate how patch laws are handled. In the intended semantics of this theory, the repository consists of one document with a fixed number $n$ of lines, and there is one basic patch, which modifies the string at a particular line. To fit this into a framework of bijections, we take the patch $\text{merge}(s_1, s_2)$ to mean “permute $s_1$ and $s_2$ at position $i$.” That is, applying this patch replaces line $i$ with $s_2$ if it is $s_1$, or with $s_1$ if it is $s_2$, or leaves it unchanged otherwise. We impose some equational laws on this patch—e.g., edits at independent lines commute. We consider an interpretation function $\text{interp}$ and a simple patch optimizer; we do not consider merge in this section, because we discuss it for the more general language in Section 6.

5.1 Definition of Patches

This patch theory is represented by the following higher inductive type:

\[
\begin{align*}
\text{space } R &\to \text{Type where} \\
&\quad \text{point constructor (patch context):} \\
&\quad \text{doc} : R \\
&\quad \text{path constructor (basic patch):} \\
&\quad \text{h@i} : (s_1 s_2 : \text{String}) (1 : \text{Fin } n) \to (\text{doc} \to \text{doc}) \\
&\quad \text{path-between-path constructors (patch laws):} \\
&\quad \text{indep} : (s : u v : \text{String}) (1 : \text{Fin } n) \to (1 \neq j) \to (s \leftrightarrow t \circ i) \circ (u \leftrightarrow v \circ j) \circ (s \leftrightarrow t \circ i) \\
&\quad \text{noop} : (s : \text{String}) (1 : \text{Fin } n) s \leftrightarrow s @ 1 = \text{refl}
\end{align*}
\]
doc should be thought of as a document with n lines (for some n fixed throughout this section). The path constructor s1 ↔ s2 @ i represents the basic patch, swapping s1 and s2 at line number i. Fin n is the type of natural numbers less than n, which we interpret here as line numbers in an n-line document (where we start numbering at 0).

For this language there are some non-trivial patch laws, which are represented by giving generators for paths between paths; we show two as an example. The equation noopt states that swapping s with s is the identity for all s; this is useful for justifying a simple optimizer, which optimizes away the two string comparisons that executing s ↔ s @ i would require. The equation indep states that edits to independent lines commute; this is useful for defining merge (x ≠ y) is the negation of x = y, i.e. (x = y) → void).

Because R is our first example of a type with both paths and paths between paths, we go over its recursion and induction principles in detail. To define a function \( f : R \to X \), it suffices to give

\[
\text{doc' : } X
\]

\[
\text{swap' : } (s1 \leftrightarrow s2 : \text{String}) \times (\text{Fin n}) \to \text{doc'} = \text{doc'}
\]

\[
\text{indep : } (s \leftrightarrow t \leftrightarrow v \leftrightarrow \text{String}) \times (\text{Fin n}) \to i \not\equiv j
\]

\[
\equiv \text{swap' s t i v j} = \text{swap' u v j o swap' s t i}
\]

\[
\text{noopt' : } (s : \text{String}) \times (\text{Fin n}) \to \text{swap' s i} = \text{refl}
\]

and then we have the following computation rules

\[
f(\text{doc}) = \text{doc'}
\]

\[
\beta1 : \text{ap f s t i} = \text{swap' s t i}
\]

\[
\beta2 : \text{PathOver} (x, x = \text{refl}) \times (\text{Fin n}) \to i \not\equiv j
\]

\[
\equiv \text{ap (ap f) (noopt s i)} = \text{ap (ap f) (noopt s i)}
\]

\[
\equiv \text{indep} \circ \text{ap (ap I) (indep s t u v i j)} = \text{GOAL1 : ua(swap(s,t) i) \equiv ua(ua(s,t) v j)}
\]

\[
\equiv \text{ap (ap I) (noopt s i)} = \text{GOAL1 : ua(ua(s,t) s i) = refl}
\]

The first computation rule is in fact a definitional equality, while the second is a path. The well-typedness of the third computation rule, which (in the latter two cases) are only propositionally equal to the cause

\[
\text{ap (ap f) (noop s i)} = \text{ap (ap f) (noop s i)}
\]

\[
\equiv \text{ua(swap(s,t) j)}
\]

\[
\equiv \text{ap (ap I) (noopt s i)} = \text{GOAL1 : ua(ua(s,t) s i) = refl}
\]

We interpret doc as Vec String n. The image of s1 ↔ s2 @ i must be a path in Type between I(doc) and I(doc)—i.e. between Vec String n and itself. For this, we choose the bijection swapat (s1,s2) i, packed up as a path in the universe using the univalence axiom. The metavariables GOAL0 and GOAL1 represent goals, that is, terms that must still be provided before the proof/program is complete. The image of indep and noopt are the goals GOAL0 and GOAL1, with the types written out above—which say that we need to validate the patch laws for the interpretation. These goals can be solved by equational properties of bijections, combined with the rules about the interaction of univalence with identity and composition described in Section 2. For example, GOAL1 is solved by observing that swapat(s,s)i is the identity bijection, and then using the fact that ua reflb = refl. GOAL0 is solved by turning both sides into a composition of bijections using the fact that ua b2 o ua b1 = ua (b2 o b1), and then proving the corresponding fact about swapat:

\[
\text{swapat-independent : } (i \not\equiv j) \to (\text{swapat}(s,t) i) \circ (\text{swapat}(u,v) j)
\]

\[
= (\text{swapat}(u,v) j) \circ (\text{swapat}(s,t) i)
\]

As above, we do not need to give cases for the group operations or prove the group laws—these come for free, from functoriality.

\[5.3 \text{ Optimizer} \]

To illustrate using the patch laws, we write a simple optimizer

\[
\text{optimize : } (p : \text{doc} = \text{doc}) \to \Sigma (q : \text{doc} = \text{doc}). p = q
\]

The type of optimize says that it takes a patch p and produces a patch q that behaves the same, according to the patch laws, as p. The goal is to optimize s ↔ s @ i to refl, saving ourselves two unnecessary string comparisons when the patch is applied. The optimizer requires analyzing the syntax of patches.

We now define two optimizations, to illustrate some different aspects of programming in homotopy type theory.

Program then prove. In this definition, we first write a function

\[
\text{optimize1 : } \text{doc} = \text{doc} \to \text{doc} = \text{doc}, \text{ and then prove that this function returns a patch that is equal, according to the patch laws, to its input. The idea is to apply the following function opt0 to each patch s1 ↔ s2 @ i:}
\]

\[
\text{opt0 : } \text{String} \to \text{String} \to \text{Fin n} \to \text{doc} = \text{doc}
\]

\[
\text{opt0 s1 s2 i = if String.equals s1 s2}
\]
To define optimize1, we generalize the problem to defining a function opt1 that acts on all of \( \mathbb{R} \), and then derive optimize1 as its action on paths (the same technique as reversing the circle in Section 2.1). This is defined as follows:

\[
\begin{align*}
\text{opt1} & : \mathbb{R} \\
\text{opt1 doc} & = \text{doc}
\end{align*}
\]

\[
\begin{align*}
\text{ap opt1 } (s_1 \leftrightarrow s_2 \circ i) & = \text{opt0 } s_1 \circ s_2 \circ i \\
\text{ap (ap opt1)} (\text{noop } s_1) & = \\
\text{GOAL0} & : \text{opt0 } s_1 \circ s_2 \circ i = \text{refl} \\
\text{ap (ap opt1)} (\text{indep } s_1 \circ s_2 \circ i) & = \\
\text{GOAL1} & : \text{opt0 } s_1 \circ s_2 \circ i \circ \text{opt0 } s_3 \circ s_4 \circ j = \text{opt0 } s_3 \circ s_4 \circ j \circ \text{opt0 } s_1 \circ s_2 \circ i
\end{align*}
\]

We map doc to doc, and apply opt0 to \( s_1 \leftrightarrow s_2 \circ i \). However, to complete the definition, we must show that the optimization respects the patch laws, via the goals GOAL0 and GOAL1 whose types are given above. The goal GOAL0 is true because \( \text{String.equals } s_1 \circ s_2 \circ i \) will be true, so, after case-analysis, refl proves that opt1 and opt0 will hold. The goal GOAL1 requires case-analyzing both \( \text{String.equals } s_1 \circ s_2 \) and \( \text{String.equals } s_3 \circ s_4 \). If both are true, the goal reduces to \( \text{refl } \circ \text{refl } = \text{refl } \circ \text{refl } \), which is true by refl. If the former but not the latter is true, the goal reduces to \( \text{refl } \circ \text{refl } \circ \text{refl } \circ \text{refl } = \text{refl } \circ \text{refl } \circ \text{refl } \), which is true by unit laws. The third case is symmetric. Finally, if neither new cases are true, then the goal holds by indep.

Next, we prove this optimization correct using R-induction:

\[
\begin{align*}
\text{opt1-correct} & : (x : \mathbb{R}) \rightarrow x = \text{opt1 } x \\
\text{opt1-correct doc} & = \text{refl} \\
\text{apd opt1-correct } (s_1 \leftrightarrow s_2 \circ i) & = \\
\text{GOAL0} & : \text{PathOver } (x. x = \text{opt1 } x) \rightarrow \text{opt0 } s_1 \circ s_2 \circ i = \text{refl} \\
\text{apd (apd opt1-correct)} (\text{noop } s_1) & = \text{GOAL0} \\
\text{apd (apd opt1-correct)} (\text{indep } s_1 \circ s_2 \circ i) & = \text{GOAL1}
\end{align*}
\]

In the case for doc, we need to give a path doc = opt1 doc, but opt1 doc is doc, so we give refl. In the case for \( s_1 \leftrightarrow s_2 \circ i \), the induction principle requires an element of the type listed above. It turns out that, by rules for PathOver, this type is equivalent to

\[
\begin{align*}
\text{apd opt1-correct } (s_1 \leftrightarrow s_2 \circ i) & = \\
\text{GOAL0} & : \text{PathOver } (x. x = \text{opt1 } x) \rightarrow \text{opt0 } s_1 \circ s_2 \circ i = \text{refl}
\end{align*}
\]

So this is where we prove that opt0 preserves the meaning of a patch. This requires two cases: when \( s_1 \equiv s_2 \), we use noop; when it is not, we use refl.

The remaining two cases require proving that this proof of correctness of opt respects the patch laws. In each case, the goal asks us to prove the equality of two proofs of equality of patches. That is, the goal has the form

\[
f_1 \equiv \text{p = doc = doc} \circ \text{q f_2}
\]

where \( p \) and \( q \) are two patches, and \( f_1 \) and \( f_2 \) are two proofs that these two patches are equal—which homotopically can be thought of as paths-between-paths, or, in more geometrically evocative terminology, as \( \text{faces between edges} \).

One might think that such a goal would be trivial, because \( f_1 \) and \( f_2 \) are representing proofs that two patches are equal according to the patch laws, and we think of patch equality as a proof-irrelevant relation. But for the definition we have given above, there is nothing that actually forces any two such faces to be identified. For example, we can compose \( \text{indep } i \neq j \circ \text{indep } j \neq i \), a proof that \( (a \leftrightarrow b \circ i) \circ (u \leftrightarrow v \circ j) \) is equal to itself, but there is no reason that this proof, which swaps twice, is necessarily the identity. Thus, although we have not considered any applications of this so far, we could potentially consider proof-relevant identifications between patches—proof-relevant patch laws. If we wished to do so, then these goals would need to be proven.

However, if we do not wish to consider proof-relevant patch equations, we can make these goals trivial by a technique called \( \text{truncation} \) [53, Chapter 7]. In this case, this means adding another constructor to \( \mathbb{R} \) of type

\[
\begin{align*}
\text{-- path-between-path-between-path constructor} \\
\text{all proofs of patch laws are equal} \\
\text{trunc } : (x : \mathbb{R}) \rightarrow (p \circ q : x = y) \rightarrow (f_1 \circ f_2 : p = q) \\
\end{align*}
\]

This constructor adds a path between any two faces \( f_1 \) and \( f_2 \)—which allows the above goals to be solved. The price for truncating is that functions defined by R-recursion/induction are only permitted when the result is also a 1-type. Fortunately, we can still define \( \text{opt1-correct} \) (because paths in a 1-type are 0-types, and therefore a 1-type) and the function \( \text{I used for \text{interp}} \) (because it interprets the point of \( \mathbb{R} \) as a set, and the collection of all sets is a 1-type). Thus, truncating \( \mathbb{R} \) would be an appropriate and helpful modification in this case.

**Program and prove.** An alternative, which requires neither truncation nor proving any equations between faces, is to simultaneously implement the optimizer, and prove that it returns a patch equal to its input. To define

\[
\begin{align*}
\text{optimize} & : (p : \text{doc = doc}) \rightarrow \Sigma (q : \text{doc = doc}) \circ p = q
\end{align*}
\]

we need to define a function on all of \( \mathbb{R} \), and derive optimize via its action on paths. However, optimize is dependently typed, and \( \text{ap f} \) for a simply-typed function \( f \) never has such a dependent type. Thus, we define a dependently typed function and use the dependent form of \( \text{ap, apd} \). Specifically, we define

\[
\begin{align*}
\text{opt } : (x : \mathbb{R}) \rightarrow \Sigma (y : \mathbb{R}). y = x
\end{align*}
\]

This type has the same shape as the type of optimize above, except it is at the level of the \( \text{points of} \mathbb{R} \) rather than the paths. Its action on paths has the following type:

\[
\begin{align*}
\text{apd opt } (p : \text{doc = doc}) : \\
\text{PathOver } (x. x : \mathbb{R}. y = x) \rightarrow \Sigma (q : \text{doc = doc}). p = q
\end{align*}
\]

When the family \( B \) is known, the type \( \text{PathOver B p b1 b2} \) can be “reduced” (via propositional equalities) to another type. In the case where \( B \) is \( x. \Sigma (y : \mathbb{R}. x = y) \), as above, the rules for path-over-a-path in \( \Sigma \)-types, constant families, and path types, yield an identification \( e \) as follows:

\[
\begin{align*}
\text{e } & : \text{PathOver } (x. \Sigma (y : \mathbb{R}. y = x)) \circ p (\text{doc,refl}) \circ (\text{doc,refl}) = \Sigma (q : \text{doc = doc}). p = q
\end{align*}
\]

Thus, if we define \( \text{opt} \) such that

\[
\text{opt doc = (doc , refl)}
\]

then

\[
\begin{align*}
\text{refl} & \\
\text{else } (s_1 \leftrightarrow s_2 \circ i)
\end{align*}
\]

\[
\begin{align*}
\text{refl} & \\
\text{refl}
\end{align*}
\]

which is the same as a path between \( p \) and \( q \) (this is what motivates the choice of \( (\text{doc,refl}) \) and \( (\text{doc,refl}) \) as the endpoints of the path-over-a-path).
and we can define optimize by composing this with e:

\[
\text{optimize} : (p : \text{doc} = \text{doc}) \rightarrow \Sigma (q : \text{doc} = \text{doc}). p = q \\
\text{optimize } p = \text{coe } (e) \text{(apd opt } p)
\]

This reduces the problem to defining opt, which we do as follows:

\[
\text{opt doc } = (\text{doc}, \text{refl}) \\
\text{opt } (s1 \leftrightarrow s2 @ i) = \text{coe e} \\
\quad \text{(if String.equals s1 s2} \\
\quad \quad \text{then (refl, noop s1 i) } \\
\quad \quad \text{else (s1 \leftrightarrow s2 @ i, refl}))
\]

We set opt doc = (doc, refl), as motivated above. For the second clause, we need a

\[
\text{PathOver } (x, y : R. y = x) p (\text{doc}, \text{refl}) (\text{doc}, \text{refl})
\]

By e, it suffices to give a

\[
\Sigma (q : \text{doc} = \text{doc}). (s1 \leftrightarrow s2 @ i) = q
\]

Thus, this is where we put the key step that we wanted to make, which is optimizing \(s1 \leftrightarrow s2 @ i\) to \(\text{refl}\) when the strings are equal, and leaving the patch unchanged otherwise—and pairing each with a proof that it is equal to \(s1 \leftrightarrow s2 @ i\).

For each of the noop and indep cases, we need to give a face between two specific paths between two specific points in the type \(\Sigma y : R. y = x\) (for some \(x\)). However, the type \(\Sigma y : R. x = y\) is in fact contractible—it is equivalent to \(\text{unit}\). Intuitively, any pair \((y, p)\) can be continuously deformed to \((x, \text{refl})\) by sliding \(y\) along \(p\); see \cite{5} Lemma 3.11.8. The identity types of any contractible type are mere propositions, so any two paths are connected by a face. Thus, because we formulated the problem as mapping into a contractible type, the remaining goals are trivial.

This definition of \(\text{opt}\), consisting of only the three cases given above, is shorter than our previous attempt. Moreover, for comparison, suppose we instead wrote this optimizer for a datatype of patches that included identity, inverses, and composition as constructors (analogous to the one in Remark \cite{4}). Then, in addition to giving the key case for optimizing \(s1 \leftrightarrow s2 @ i\) we would need to give inductive cases describing how the optimizer acts on identity, inverses, and composition. Here, because the optimizer can be defined as a group homomorphism, we need to give only the “interesting” case; the inductive cases are provided by the framework.

**Singleton Types and Computation**  Because the type \(\Sigma (y : A). x = y\) is contractible, we can think of it as a *singleton type*, written \(S(x)\). It consists of “everything in \(A\) that is equal to \(x\)” or, more precisely, a point in \(A\) with a path to \(x\). One may well wonder what is the point of writing a function into a contractible type? Using the singleton notation we have

\[
\text{optimize } : (p : \text{doc} = \text{doc}) \rightarrow S(p).
\]

Because \(S(p)\) is contractible, and hence equivalent to \(\text{unit}\), isn’t this just a triviality? The answer is “no” because even if two elements of a type are connected by a path (and hence cannot be distinguished by any other operation of type theory), the type nevertheless has meaningful computational content in that we may observe its output when it is run and thereby make distinctions that are obscured within the theory.

Thus, even though the \text{optimize} function that we wrote above is equal (i.e., homotopic) to the function that simply returns \(p\) itself—or, indeed, any other function with that type—we expect, based on work on the computational interpretation of homotopy type theory, that it will in fact compute appropriately—e.g., \text{optimize } (s \leftrightarrow s @ i) will in fact return \text{refl} because of the way it is programmed. This is consistent with prior experience with, for example, function extensionality in type theory \cite{6}. A higher-order computation will compute a particular function, not any function with the same graph; computation does not respect extensional equality of functions.

### 6. A Patch Theory With Richer Contexts

In the previous section we considered patches of the form \(s1 \leftrightarrow s2 @ i\), which naturally induce total bijections on the type of n-line documents. In Section 5 we exploited this fact to model these patches as paths in a higher inductive type, using univalence to map them to bijections on Vec String n. Now we will consider a richer language of patches—inserting a string \(s\) as the 2th line in a file (ADD \(s@0\)), and removing the 1th line of a file (RM 1). These patches only make sense in certain situations. For example, the only patch applicable to an empty file is ADD \(s@0\); to the resulting file we may apply one of ADD \(s@0\), ADD \(s@1\), or RM 0, which respectively add \(s\) before or after \(a\), or deletes \(a\).

A suitable patch theory must express such constraints on composition using contexts. More than one context is required, because not all patches are composable with one another. For example, it makes sense to classify repositories by the number of lines they contain so that removal from an empty file is ruled inadmissible by the patch theory. This may be achieved by defining the contexts (the points of \(R\)) to be of the form doc \(n\), where \(n\) is of type Nat. The patch that adds a line is, generally in \(R\), a path in \(R\) witnessing \(doc n+1 = doc n\). Although this formulation expresses necessary constraints on the use of the primitive patches, it fails to admit the obvious interpretation of doc \(n\) as the type of n-line files, Vec \(n\) String. The difficulty is that the type theory demands that the interpretation respect paths, and we have \(doc n = doc n+1\) in \(R\), yet the types Vec \(n\) String and Vec \(n+1\) String are not bijective, and hence are not equated by univalence.

To motivate what follows, let us observe that we may expect there to be an “initial” context describing the empty repository, the initial state of a repository. Because there is only one empty repository, the empty file, we would expect the interpretation of the initial context to be a contractible type whose element is the empty file. Moreover, we would expect there to be a path from the initial context to every other context, based on the idea that it should be possible to reach every repository state by some sequence of patches. Thus, every context would be equal to the initial context, and by functoriality and univalence all contexts must be modeled by a contractible type.

Given that the interpretation of a context should be a type containing repository files as elements, its contractibility, together with univalence, suggest that each context be modeled by the singleton type, \(S(\text{file})\), containing only the file in question. But if the meaning of a context is to be such a singleton, the context must essentially determine the contents of the repository. The obvious way to achieve this is to consider contexts of the form doc \(n\) file, where \(n\) is, as before, the number of lines, and \(\text{file}\) is a file of that length, an element of Vec \(n\) String. The patch ADD \(s@0\) would then be a path doc \(n\) file = doc \(n+1\) file’, where file’ is the result of adding \(s\) at line \(l\) in file, and similarly for RM \(l\). We can interpret doc \(n\) file as \(S(\text{file})\) functionally, because any two singletons, being contractible, are equivalent types, and hence equal by univalence.

The trouble with this formulation is that it intermixes the abstract theory of patches with its concrete realization as a file. Although we reject it as a solution, it does suggest another, more satisfactory, formulation. The main idea is that the contexts need only determine the contents of the repository, not literally contain them, in order to construct the singletons model. This is achieved.
by indexing contexts by patch histories, which are sequences of 
composable patches applicable to files of a given length. With re-
spect to any particular realization of patches, a history applicable to 
the empty file uniquely determines the resulting file’s contents. As 
an added benefit, histories also reify sequences of patches in a way 
which facilitates certain operations on repositories, such as moving 
forward or backward in time.

Patch contexts may be understood as types for patches, limiting 
how they may be composed, and we expect these to be erasable at 
run-time. This will require us to compute views of identity types 
that are more amenable to computation, similarly to the way in 
which we used the characterization of the loop space of the circle 
in Section 4.

6.1 Definition of Patches
Let History m n be the type of history (sequences of 
patches) applicable to m-line files which result in n-line files. We 
will define History m n as a quotient higher inductive type to 
equate sequences of patches which result in the same changes to 
a file. For example, two additions in sequence can be commuted if 
the line numbers are shifted.

space History : Nat → Nat → Type where 
-- point constructors: [] : History m m 
ADD_0 : (m n : Nat) (s : String) (l : Fin n+1) → 
History m n → History m n+1 
RM_0 : (m n : Nat) (l : Fin n+1) → 
History m n+1 → History m n 
-- path constructors: 
ADD-ADD-< : (m n s1 s2 : Nat) (l1 l2 : Fin n+1) (s1 s2 : String) (h : History m n) → 
ADD s1 @ l1 :: ADD s2 @ l2 :: h 
≥ 
ADD s1 @ l1 :: ADD s2 @ (l2-1) :: h 
≥ 
ADD s1 @ (l1+1) :: ADD s2 @ l2 :: h 
≥ 
ADD s1 @ l1 :: ADD s2 @ (l2-1) :: h

(For the sake of clarity we have omitted some coercions 
between different Fin types.) To simplify the code in the remainder 
of this section, we have omitted the paths commuting ADD-RM, RM-
ADD, and RM-RM, which can be defined in exactly the same way.

Histories applicable to the empty file (elements of History 0 n) uniquely identify files because the history can be “replayed” from the start. These complete histories will serve as the patch contexts in this language—the domain of a patch is a complete 
history identifying a file to which the patch is applicable, and the 
codomain is the domain history extended by the patch which was 
just applied.

space R : Type where 
-- point constructor: 
doc : {n : Nat} → History 0 n → R 
-- path constructors: 
addP : (s : Nat) (s : String) (l : Fin n+1) 
(h : History 0 n) → ADD s @ l :: h 
rmP : (n : Nat) (l : Fin n+1) 
(h : History 0 n+1) → doc h = doc (ADD s@l :: h)

Next, we would like to insert faces equating commuting se-
quences of patches, but our definition of histories means that no dif-
fering sequences of paths will ever be parallel! For example, when 
11 < 12, the two paths

addP s2 12 o addP s1 11
: h = ADD s2@12 :: ADD s1@11 :: h
addP s1 11 o addP s2 12
: h = ADD s1@11 :: ADD s2@12 :: h

ought to be “equal” as patches, but it does not even make type sense 
to state this equation. We rely on the fact that histories are quo-
tiented by the same commutation laws—that is, we already equated 
those exact elements of History 0 n with the path ADD-ADD-<.
Therefore, we can stipulate that the above two paths are equal over 
the ADD-ADD-< equation from History 0 n, with respect to the 
type family x.h = x. Thus the faces of R are defined as follows:

addP-addP-< : {n : Nat} (l1 : Fin n+1) (l2 : Fin n+2) 
(s1 s2 : String) (h : History 0 n) → 11 < 12 → 
PathOver (x.doc h = doc x) ADD-ADD-<
(addP s2 l2 o addP s1 11)
(addP s1 11 o addP s2 12)

addP-addP-≥ : {n : Nat} (l1 : Fin n+1) (l2 : Fin n+2) 
(s1 s2 : String) (h : History 0 n) → 11 ≥ 12 → 
PathOver (x.doc h = doc x) ADD-ADD-≥
(addP s2 l2 o addP s1 11)
(addP s1 11 o addP s2 12)

6.2 Interpreter
Assume we have functions add and rm which implement our 
patches on concrete vectors of Strings.

add : {n : Nat} (s : String) (l : Fin n+1) 
→ Vec String n → Vec String n+1
rm : {n : Nat} (l : Fin n+1) 
→ Vec String n+1 → Vec String n

We want to define a function I : R → Type which models, or 
interprets, points of R (complete histories) as types, and paths of 
R (patches) as bijections between those types. Then we can define 
interp p = coe-bijection (ap I p) and obtain

interp : {n1 n2 : Nat} (h1 : History 0 n1) 
(h2 : History 0 n2) → (doc h1 = doc h2) 
→ Bijection (I (doc h1)) (I (doc h2))

with the idea that interp (addP s 1 h) should in some sense be 
add s 1, and interp (rmP 1 h) should be rm 1.

The type of interp has gotten more complex than before, 
because there are now many patch contexts, instead of the single 
doc. As a result, we must choose the interpretation of each doc h 
into the type universe.

As we discussed at the beginning of this section, we cannot 
simply interpret doc h as Vec String n, because these types are 
not bijective. Instead, we will essentially interpret doc h as the 
exact file which arises from applying the patches in h. That is, we 
will record in its type exactly which file is described by this history, 
rather than simply regarding it as a plain text file.

We can specialize any function f : A → B to a function be-
tween singleton types, as follows:

tosingleton : (f : A → B) → (M : A) → S(M) → S(f M) 
tosingleton f (x,p) = (f x, ap f p)

Because singleton types are contractible (contain exactly one point, 
and have trivial higher structure), every function between singleton 
types is automatically a bijection. Call this fact single-biject. 
Then we can define the interpretation

I : R → Type
I (doc h) = S(replay h)
ap I (addP s 1 h) = 
ua (single-biject (tosingleton (addP s 1 h)))
ap I (rmP 1 h) = ua (single-biject (tosingleton (rmP 1 h)))
apd' (ap I (addP-addP-< 11 12 s1 s2 h p)) = 
<replay respects this patch law>
apd' (ap I (addP-addP-≥ 11 12 s1 s2 h p)) = 
<replay respects this patch law>
where \( \text{apd}' \) is a function which gives the action of a function on a Path\( \Delta \) (we omit the details, since they will not be used below), and \( \text{replay} \) is a function which steps through a complete history to compute the file specified by that history:

\[
\text{replay} : \{n : \text{Nat}\} \to \text{History} \ 0 \ n \to \text{Vec} \ \text{String} \ n
\]

\[
\text{replay} \ [\ ] = [\ ]
\]

\[
\text{replay} \ (\text{ADD} s @ 1 :: h) = \text{ADD} s 1 (\text{replay} h)
\]

\[
\text{replay} \ (\text{RM} l :: h) = \text{RM} 1 (\text{replay} h)
\]

\[
\text{ap} \ \text{replay} \ (\text{ADD}-\text{ADD} < 11 \ 12 \ s1 \ s2 \ h \ p f) = \ \text{GOAL0} : \text{add} s2 12 \ (\text{add} s1 11 \ (\text{replay} h))
\]

\[
\text{ap} \ \text{replay} \ (\text{ADD}-\text{ADD} > 11 \ 12 \ s1 \ s2 \ h \ p f) = \ \text{GOAL1} : \text{add} s2 12 \ (\text{add} s1 11 \ (\text{replay} h)) = \text{add} s1 11+1 \ (\text{add} s2 12 \ (\text{replay} h))
\]

Because histories are quotiented by the commutation laws, we must prove in \( \text{GOAL0} \) and \( \text{GOAL1} \) that \( \text{replay} \) sends equal histories to equal files, which amounts to showing that \( \text{replay} \) satisfies the same laws as \( \text{ADD} \).

The implementation of \( \text{replay} \) is needed during typechecking of the definition of \( \text{ap} \ I' \ (\text{addP} s @ 1 h) \), which must be in Biject \( S(\text{replay} h)\) \( S(\text{replay} (\text{ADD} s @ 1 :: h)) \). By unrolling the definition of \( \text{replay} \), the latter type is \( S(\text{add} s 1 (\text{replay} h)) \).

### 6.3 Logs

The interpreter above suggests that one may implement a version control system in homotopy type theory by storing sequences of patches as paths, and repositories as vectors of strings. A repository can be updated by running \( \text{interp} \) on a new patch. Note that, although the types of the paths include histories which redundantly encode the patch data, these types are only needed to compute the singleton type of the file data, which is not needed at runtime; the file data itself is computed only from the patches themselves. Thus, it would be sensible to discard the histories at runtime, through some erasure mechanism.

Another feature we might like to implement is the ability to print out an explicit representation, or \( \text{log} \), of all the patches that have been applied to the repository. Logs can’t be generated directly from the changes induced by patches on the repository, because we cannot inspect the intentions of functions \( S(\text{file}) \to S(\text{file}') \).

Instead, just as we computed changes on repositories by interpreting points of \( R \) as singleton files, we can compute the changes induced on histories through an alternate interpretation of points of \( R \) as singleton histories:

\[
I' : R \to \text{Type}
\]

\[
I' \ (\text{doc} h) = S(h)
\]

\[
\text{ap} \ I' \ (\text{addP} s 1 h) = \ ua \ (\text{single-biject} \ (\text{tosingleton} \ (h \to S(\text{file}'))))
\]

\[
\text{ap} \ I' \ (\text{rmP} l h) = \ ua \ (\text{single-biject} \ (\text{tosingleton} \ (h \to R M \ 1 :: h)))
\]

\[
\text{apd}' \ (\text{ap} I') \ (\text{ADD}-\text{ADD} < 11 \ 12 \ s1 \ s2 \ h \ p) = \text{ADD} \text{ADD} < 11 \ 12 \ s1 \ s2 \ h \ p
\]

\[
\text{apd}' \ (\text{ap} I') \ (\text{ADD}-\text{ADD} > 11 \ 12 \ s1 \ s2 \ h \ p) = \text{ADD} \text{ADD} > 11 \ 12 \ s1 \ s2 \ h \ p
\]

\[
\text{interpH} : \text{doc} h = \text{doc} h' \to S(h) \to S(h')
\]

\[
\text{interpH} \ p = \text{coe} \ (\text{ap} I' \ p)
\]

Then \( \text{interpH} \) takes a patch \( p \), which updates the repository history \( h \), to the history \( h' \) which results from applying the patch \( p \). As with \( \text{interp} \), this function computes updates to the repository representation without relying on the endpoints (contexts)—this shows that we could recover a history from a patch (and an initial history), if we were to erase histories at run-time.

\( I' \) is a good example of the benefit of functorial semantics—both \( I \) and \( I' \) are models of the patch theory \( R \), and the natural functoriality of functions in homotopy type theory ensures that both validate all the patch laws of the theory.

### 6.4 Merge

In Section 4, we said that \( \text{merge} \) takes any pair of diverging patches to a pair of converging patches that reconciles them. Our definition of \( \text{merge} \) in Section 4 accepted arbitrary pairs of patches, because that patch theory had a single context \( \text{num} \).

Now that we have history-indexed patches, we might expect \( \text{merge} \) to take a pair \( (\text{doc} h = \text{doc} h1) \times (\text{doc} h = \text{doc} h2) \) and, if a merge is possible, produce a pair \( (\text{doc} h1 = \text{doc} h?) \times (\text{doc} h2 = \text{doc} h') \). However, as discussed in Section 4 even though some divergent patches are impossible to reconcile automatically—for example, given \( \text{addP} s 0 \) and \( \text{addP} s' 0 \), we have no reason to favor either \([s,s']\) or \([s',s]\) over the other—we can produce a valid merge that simply undoes both edits. Therefore merge can be a total function that always returns a pair of patches \( (\text{doc} h1 = \text{doc} h?) \times (\text{doc} h2 = \text{doc} h') \). A user-friendly system might recognize when merge undoes the edits, indicating a merge conflict, and prompt for manual intervention.

Defining such a function requires a “view” or derived recursion principle for these types, as we illustrated in Section 4. The History type characterizes the “forward-pointing” paths in \( R \) as sequences of composable primitive patches \( \text{ADD} \) and \( \text{RM} \), modulo patch laws. But to define such a \( \text{merge} \) we would also need a characterization of, for example, the type of the path \( ! (\text{rmP} l' h) \).

\[
\text{doc} \ n \ (R M \ 1' :: h) = \text{doc} \ (n+1) \ h
\]

The type \( \text{History} \ n \ n+1 \) does not characterize this type, because the only elements of \( \text{History} \ n \ n+1 \) lengthen the history \( h \) (by prepending sequences of \( \text{ADDs} \) and \( \text{RM}s \)), while this path shortens it. In other words, a history contains only compositions of primitive patches, and not their inverses. On the other hand, a merge involving inverse paths is not sensible in this patch theory. Although \( ! (\text{rmP} l' h) \) and \( \text{addP} s 1 \) \( R M \ 1' :: h) \) have a common domain of \( \text{doc} \ (R M \ 1' :: h) \), the former is not part of the patch theory we are studying; instead, it was imposed by the natural symmetry of identity types.

We can avoid these undesirable inverses by restricting merge to divergent paths with shared domain \( \text{doc} [\ ] \). This ensures that a patch \( p \) to be merged can be mapped to a complete history \( \text{interpH} \ p \ [\ ] \). Users of a version control system will always encounter compositions of generating patches starting from the empty file, so this restriction does not come up in practice.

\[
\text{merge} : \{n1 n2 : \text{Nat}\}
\]

\[
\begin{align*}
(h1 : \text{History} \ 0 n1) & \ (h2 : \text{History} \ 0 n2) \\
(\text{doc} [\ ] = \text{doc} h1) & \ (\text{doc} [\ ] = \text{doc} h2) \\
\Sigma(n' : \text{Nat}) & \ (\Sigma(h' : \text{History} \ 0 n')) \\
(\text{doc} h1 = \text{doc} h') & \ (\text{doc} h2 = \text{doc} h')
\end{align*}
\]

Because this \( \text{merge} \) is more intricate than the one considered in Section 4, we will convert the input paths to complete histories using \( \text{interpH} \), then define a function \( \text{mergeH} \) which computes merges of complete histories, and convert the resulting histories back into paths.

To reconcile two divergent complete histories, we define a notion that a history \( h2 \) has \( h1 \) as a prefix (or \( h2 \ extends \ h1 \)):

\[
\text{Extension} : \{n1 \ n2 : \text{Nat}\} \to \text{History} \ 0 n1 \to \text{History} \ 0 n2 \to \text{Type}
\]

\[
\text{Extension} \ h1 \ h2 = \Sigma(s : \text{History} \ n1 n2). \ h1 ++ s = h2
\]
Here, \( ++ : \text{History } n1 \ n2 \rightarrow \text{History } n2 \ n3 \rightarrow \text{History } n1 \ n3 \) appends two histories. Then, if we have a pair of complete histories \( h_1, h_2 \), we reconcile them by returning a history \( h' \) which extends both \( h_1 \) and \( h_2 \). The suffixes of \( h_1 \) and \( h_2 \) yielding \( h' \) are the pair of converging patches produced by the merge.

\[
\text{merge} : \{n \ n2 : \text{Nat}\} \\
(\text{h}_1 : \text{History } 0 \ n1) \ (\text{h}_2 : \text{History } 0 \ n2) \rightarrow \\
\Sigma(n' : \text{Nat}). \ \Sigma(h' : \text{History } 0 \ n'). \\
\text{Extension } h_1 \ h' \times \text{Extension } h_2 \ h'.
\]

Once we have defined \( \text{merge} \), we can convert its output back to paths. A complete history can be transformed into a path \( \text{doc} \) by repeated concatenation:

\[
\text{toPath} : \{n : \text{Nat}\} (h : \text{History } 0 \ n) \rightarrow \text{doc} \ [\ ] = \text{doc} \ h \text{ by repeated concatenation}:
\]

\[
\text{toPath} \ [\ ] = \text{refl}
\]

\[
\text{toPath} \ (\text{ADD n} \ h \ h' ) = \text{addP} \ s \ l \circ \text{toPath} \ h'
\]

\[
\text{toPath} \ (\text{RM } l \ h \ h' ) = \text{rmP} \ l \circ \text{toPath} \ h'
\]

To turn an \( \text{Extension } h \ h' \) into a path, we need only travel from \( \text{doc} \ h \) to \( \text{doc} \ [\ ] \) and back to \( \text{doc} \ h' \):

\[
\text{extToPath} : \{n' : \text{Nat}\} \\
(\text{h} : \text{History } 0 \ n) \ (\text{h'} : \text{History } 0 \ n') \rightarrow \\
\text{Extension } h \ h' \rightarrow \text{doc} \ h = \text{doc} \ h'.
\]

\[
\text{extToPath} \ [\ ] = (\text{toPath} \ h') \circ \text{toPath} \ h
\]

\[
\text{extToPath} \text{ completely ignores the extension itself; intuitively, this is possible because extensions are more informative than paths, since the former contain only compositions of generators.}
\]

Combining these ingredients, we define \( \text{merge} \) as:

\[
\text{merge} \ p1 \ p2 = \\
\text{let } (n', (h', (e1, e2))) \Rightarrow \\
\text{mergeH} (\text{interpH} \ p1 [\ ]) (\text{interpH} \ p2 [\ ]) \\
\text{in } (n', (h', (\text{extToPath} \ e1, \text{extToPath} \ e2)))
\]

This shows that \( \text{merge} \) reduces to \( \text{mergeH} \). We have not yet defined \( \text{mergeH} \), but we can reduce it to defining a merge on simple text files. Because \( \text{History } 0 \ n \) is quotiented by patch laws, we must show that \( \text{mergeH} \) sends equal histories to equal results. One way to handle this is to choose a representative for each equivalence class of histories, and then compute on these representatives. Here, we can use the function \( \text{replay} \) to convert each \( \text{History } 0 \ n \) to its file contents in \( \text{Name} \ \text{String} \). Then, we could define a merge function directly on files (perhaps using existing algorithms), and then compute extensions of the input histories which result in that those files. Such a \( \text{mergeH} \) would necessarily respect the patch laws because \( \text{replay} \) does.

7. Related Work

Several prior category-theoretic analyses of version control have been considered. Jacobson [16] interprets patches in inverse semigroups, where they are essentially partial bijections. Mimram and Di Giusto [28] analyze merging as a pushout, which provides a canonical merge for every pair of patches, including a primitive representation of merge conflicts. Houston [15] also discusses merge as pushout, and a duality with exceptions. Our contribution, relative to these analyses, is to present patch theory in a categorical setting that is also a programming formalism, so it directly leads to an implementation. These analyses consider settings where not all maps are invertible. In homotopy type theory all identity types are symmetric, and to fit patch theories into this symmetric setting, we either considered a language where all patches were naturally total bijections on any repository (Section 6 and 7), or used types to restrict patches to repositories where they are bijections (Section 6).

Dagit [10] presents an approach to proving some invariants of a version control implementation using advanced features of Haskell’s type system. Camp (Commutate And Merge Patches) [7] is an experimental version control system based on Darcs; the Camp project aims to prove the correctness of its patch theory in Coq. We have not yet mechanized the programs described here, but our work provides another possible path to formalization.

Swierstra and Löh [34] explore the use of separation logic [30] for specifying the behavior of patches. In Section 6, we took repository contexts to be patch histories, but it would be interesting to consider using separation logic formulas to describe histories, which would allow for small-footprint specifications of patches.

8. Conclusion

Inspired by the patch theory of Darcs [12], which emphasizes the groupoid structure of patches, we have explored the formulation of patch theory within the framework of homotopy type theory. Patch theories are given as higher inductive definitions in which we specify generators for the points (path contexts), 1-dimensional paths (patches), and 2-dimensional paths (patch laws). The groupoid laws come “for free”, and so need not be specified explicitly. An idealized implementation of a patch theory is given by a function mapping the patch theory into a univalent universe of sets and bijections. The sets are concrete repositories and the bijections are the actual actions of the patches on repositories. The mapping is intrinsically functorial, and hence must respect the intrinsic groupoid structure, but is given by the elimination principle for higher-inductive types, which demands that patches be realized by bijections satisfying the patch laws.

Besides these general structural considerations, some homotopy-theoretic concepts play a role in the development. In particular the “encode/decode” functions used to characterize identity types [23, 35] here become an implementation technique. For example, to define the merge of a span of patches (that is, a pair of paths with a common domain), we first pass to a concrete representation of paths, define the merge on the representation, and then pass back to a reconciliation, a cospan of patches (a pair of patches with common codomain) in the identity type. Other interpretations of a patch theory are definable in a similar manner, providing operations, such as logging, of practical interest for revision control.

There is much more to be done. Most importantly, the development of the merge operation in Section 6 is incomplete, because we have not proved the required properties of it. There we define \( \text{merge} \) using a partial characterization of the identity type of \( R \) as complete histories. Defining functions in either direction is sufficient to pass between these two representations, but not to prove properties of \( \text{merge} \) via properties of \( \text{mergeH} \), such as the merge laws. For this, a more precise characterization is needed, namely an inductive type which is equivalent to the identity type, as \( Z \) is to the identity type of the circle. We leave this to future work.

More broadly, the computational interpretation of homotopy type theory must be developed further, including a fuller understanding of the interplay between definitional equality, propositional equality, and computation, and an understanding of what type erasure would mean in that setting. This includes developing a fuller understanding of “sub-homotopical” computation, meaning the mapping into contractible types.
quire a complete characterization of the space of spans of patches. One direction for future work is to study this problem using the tools of homotopy theory to characterize such spans in a way that is amenable to our purposes. Another is to develop a type theory with non-symmetric paths (as suggested by [21]) grounded in directed homotopy theory, where we could formulate theories of partial patches without refining their contexts, which might simplify the development in Section 6.

Acknowledgments We thank the participants of the 2013 IFIP WG 2.8 meeting for helpful conversations about this work, and the anonymous reviewers for their helpful feedback on this article.

A. Addendum

In this addendum, we expand on the relationship among the patch theories considered in the main body of the paper, and clarify the role of histories in defining and analyzing the patch theory given in Section 6. These points were omitted from the published version for lack of time and space.

A.1 Interval

Presenting the patch theories of Sections 4 and 5 as higher inductive types automatically added useful inverse patches to the theory. For example, in Section 4, we only specified a path constructor for the add-one patch add1, but the subtract-one path (! add1) was provided for free.

PathOver expressed the contractibility of identity types. In particular, we argued that inverse patches were undesirable in that setting, and restricted our attention to paths doc 0 = doc n. To see why this effectively eliminates inverse paths from consideration, let us explore the unit interval, a simple but analogous example.

The unit interval is a higher inductive type defined as:

```
space I : Type where
center : I
zero : I
seg : zero = one
```

We can regard I as a path theory with two contexts zero and one, and one patch seg, which sends zero to one.

As usual, paths in I are automatically endowed with identities, inverses, and composition. Nevertheless, zero = one has no more elements than we put in—all paths of that type are homotopic to seg. Intuitively, this is because (! seg) goes “backwards” from one to zero, so any sequence of compositions yielding a path zero = one must have one more seg than (! seg). For example,

```
seg 0 = seg 0 = seg 0 = one
```

but groupoid laws equate this to zero.

To prove this result, we will first show that I is contractible. It suffices to exhibit a point in I, the center of contraction, together with a proof that every point in I is equal to the center:

```
(x : I) → center = x
```

In this case, we choose the center to be zero.

```
is-contr : (x : I) → zero = x
```

```
is-contr zero = refl
```

```
is-contr one = seg
```

```
and is-contr seg = refl(seg) : PathOver x. zero = x seg refl seg
```

The last clause demands that the choice of path given by \texttt{is-contr} is continuous in the choice of codomain. That \texttt{PathOver} reduces to the type seg = seg, by the rules for path-over-a-path in identity types; this is true by \texttt{refl(seg)}.

Since \texttt{I} is contractible, it is also a mere proposition, and so all its identity types are contractible [15, Lemma 3.11.1]. In particular, to prove that seg is the unique element of zero = one up to homotopy, we can look at the action on paths of \texttt{is-contr}.

```
apd is-contr ((a b : I) : p : a = b) → PathOver x. zero = x p (is-contr a) (is-contr b)
```

If we specialize this to paths zero = one, we get

```
apd is-contr (zero) (one) : (p : zero = one) → PathOver x. zero = x p refl seg
```

This \texttt{PathOver} reduces to \texttt{p = seg}, yielding

```
apd is-contr (zero) (one) : (p : zero = one) → p = seg
```

which is a proof that all paths zero = one are homotopic to seg.

A.2 Open Interval

Let us extend the unit interval example by considering patch contexts indexed by natural numbers. The resulting open interval is a higher inductive type defined as:

```
space I* : Type where
doc : Nat → I*
doc 0 = doc n
add1 : (n : Nat) → doc n = doc n+1
```

Topologically, I* is the real half-line \([0, \infty)\). This is similar to the universal cover of the circle, discussed in Section 4.1, which corresponds to \((-\infty, \infty)\).

As a patch theory, I* has Nat-indexed contexts, and a patch from doc n to doc n+1 for each n. The idea is that I* is the theory of natural number repositories, and the add1 patch increments a repository’s contents. As with the unit interval, inverse paths do not add any additional paths from doc 0 = doc n up to homotopy, the only way to get from the empty document doc 0 to a document doc n is to apply the add1 patch n times. Hence, the codomain context doc n determines exactly which sequence of patches has occurred.

Note that this did not occur in Section 4, where we had a single patch context doc. Here, we have chosen more expressive contexts to track a repository’s history—in this case, this only requires counting how many times we have applied the only applicable patch. (These patch contexts coincide with the repository contents, but that is not true in general.)

To prove there is a unique path doc 0 = doc n, we show that I* is contractible with center doc 0. As with I, it follows that doc 0 = doc n is also contractible.

We prove \texttt{I*} is contractible by \texttt{I*}-induction, which means that if it suffices to show that, for any number \(n\), we can construct a path \texttt{doc 0 = doc n} by composing \texttt{add1} with itself \(n\) times, and moreover, this choice of paths is continuous in the choice of codomain.

```
toPath : (n : Nat) → doc 0 = doc n
toPath 0 = refl
ntoPath (n+1) = add1(n) o toPath n
```

```
is-contr : (x : I*) → doc 0 = x
```

```
is-contr (doc n) = toPath n
```

```
apd is-contr (add1 n) = refl
```

```
PathOver x. doc 0 = x (add1 n) (toPath n) (toPath n+1)
```

This last \texttt{PathOver} reduces to

```
(add1 n) o (toPath n) = toPath n+1
```

which, once we expand the definition of \texttt{toPath n+1}, is true by \texttt{refl}.

The type of paths starting at doc 0 is

```
Σ (n : Nat). doc 0 = doc n
```

This classifies pairs of a number and a path doc 0 = doc n, but the latter type is contractible, so it contains no additional information. Therefore, this type is isomorphic to Nat—that is, patches applicable to doc 0 are characterized precisely by the index n of their codomain context doc n. This makes sense because there is only one path doc 0 = doc n.

A.3 Binary Trees

In analogy to Section 6, we will extend our running example to allow two distinct edits at each patch context, add \texttt{true} and add \texttt{false}. Again, we will index patch contexts by histories—in this
case, lists of booleans indicating the sequence of patches applied to the repository. The edit `add x` thus prepends `x` to each history.

```haskell
space R : Type where
doc : Bool List → R
add : (x : Bool) {xs : Bool List} → doc xs = doc x::xs
```

Now the patch theory looks like a tree, where the nodes are histories and the paths label the edges. For example,

```haskell
merge : {l1 l2 : Bool List} → doc l1 = doc l2 → doc [] = doc xs
```

As discussed in Section 5, we want to prove that `merge` produces commuting squares, and that it is symmetric:

```haskell
symmetric : {l1 l2 l : Bool List} → doc l = doc l1 → doc l2 = doc l 
```

The symmetric law reduces to the symmetry of `mergeH`. Given a proof

```haskell
symmetricH : {l1 l2 l : Bool List} → mergeH l1 l2 = mergeH l2 l1
```

A.4 Quotiented Binary Trees

To complete the analogy to Section 6, we will extend this example once more, this time with patch laws. For simplicity, we will say that any two patches commute.

In the binary tree patch theory, `Bool Lists` were an inductive characterization of patches from the initial repository, as those paths were compositions of `add true` and `add false`. Here, since patch composition commutes, we must quotient `Bool Lists` by permutation.

This yields the type of boolean multisets, lists quotiented by "Ex"change of adjacent elements, defined as the following quotient higher inductive type:

```haskell
space MS : Type where
false : MS
true : MS
```

We index patch contexts by `MSes`, rather than `Bool Lists`. As before, patches preprend a boolean to the context.

```haskell
space R : Type where
doc : MS → R
add : (x : Bool) {xs : MS} → doc xs = doc x::xs
```

The `ex` constructor implements the patch laws, for example, equating `add true o add false` and `add false o add true`. It creates paths-over-paths because the equated patches have different types:

```haskell
add true o add false = doc xs = doc true::(false::xs) 
add false o add true = doc xs = doc false::(true::xs)
```

However, `true::(false::xs)` and `false::(true::xs)` are equal as multisets, by virtue of `Ex true false xs`. Thus, the patch law `ex true false xs` equates compositions of patches over the fact that their right endpoints are equal.

Now we will show that `R` is contractible. Patch laws significantly complicate the proof; in fact, one might even expect `R` to have non-
To prove $R$ is contractible, we first construct a path $\text{doc} [] \Rightarrow \text{doc} s$ for each multiset $s$. Because $\text{MS}$ is a quotient type, we must show that this map respects the quotient.

$$\begin{align*}
toPath : (xs : \text{MS}) & \to \text{doc} [] \Rightarrow \text{doc} xs \\
toPath [] & = \text{refl} \\
toPath (x::xs) & = \text{add} x \circ \text{toPath} xs \\
apd \text{toPath} : (\text{Ex} x y xs) & \Rightarrow \text{GOAL0} \\
& : \text{PathDiv} (s, \text{doc} [] \Rightarrow \text{doc} s) (\text{Ex} x y xs) \\
& \Rightarrow (\text{toPath} (x::y::xs)) \Rightarrow (\text{toPath} (y::x::xs))
\end{align*}$$

$\text{MS}$-induction automatically demands this of us, in the form of the third clause. Expanding the definition of $\text{toPath}$, $\text{GOAL0}$ has type $\text{PathDiv} (s, \text{doc} [] \Rightarrow \text{doc} s) (\text{Ex} x y xs) (\text{toPath} (x::y::xs)) (\text{toPath} (y::x::xs))$.

By path-over-a-path rules, this reduces to

$$\begin{align*}
\text{ap} \text{doc} (\text{Ex} x y xs) \circ (\text{add} x \circ (\text{add} y \circ \text{toPath} xs)) \\
& = (\text{add} y \circ (\text{add} x \circ \text{toPath} xs))
\end{align*}$$

But this is exactly the type of $\text{ex} x y xs$, once we expand the $\text{PathDiv}$. This completes our definition of $\text{toPath}$. Morally, this subgoal—that $\text{toPath}$ respects the path constructor of $\text{MS}$—verifies that $\text{ex}$ fills in the loops we discussed above. Indeed,

$$\begin{align*}
apd \text{toPath} : (xs : \text{MS}) (p : xs = ys) & \to \text{PathDiv} (h, \text{doc} [] \Rightarrow \text{doc} h) p \Rightarrow (\text{toPath} xs) \\
is a proof that, whenever $xs$ and $ys$ are equal multisets, then there is a disc whose boundary is formed by $\text{toPath} xs$, $\text{doc} xs = \text{doc} ys$, and $\text{toPath} ys$.

Now that we have defined $\text{toPath}$, we can prove that $R$ is contractible with center doc $[]$: $\text{is-contr} (r : R) \Rightarrow \text{doc} [] = r$.

As before, the second clause is true by $\text{refl}$, using path-over-a-path reductions and the definition of $\text{toPath}$. The subgoal in the third clause is rather complicated as it involves paths over paths-over-paths; we have a machine-checked proof of this,

$$\text{R}$$ but will not discuss it further here.

---

A.5 Merge Laws For Richer Contexts

We would like to end by inductively characterizing the paths in the patch theory of Section 6 and using this characterization to prove the merge laws for the merge operation given in Section 6.4.

The first step will again be to prove that this $\text{R}$ is contractible. The proof is essentially the same as in the previous subsection; the only difference is that this patch theory has more complex patches and path laws. Again, we have a machine-checked proof that (a generalized form of) $\text{R}$ is contractible.

Thus, let us start with a proof that $\text{is-contr} n \Rightarrow \text{doc} [] = \text{doc} h$.

By apd $\text{is-contr}$, identity types in $\text{R}$ are also contractible, so paths in $\text{R}$ are uniquely determined by their endpoints. Thus, the type of paths starting at doc $[]$,

$$\Sigma (n : \text{Nat}). \Sigma (h : \text{History 0 n}). \text{doc} [] \Rightarrow \text{doc} h$$

equivalent to

$$\Sigma (n : \text{Nat}). \text{History 0 n}$$

because the path provides no additional information.

By univalence, all constructions respect equivalence of types; therefore, a merge operation on complete histories suffices to merge paths, and a proof of the merge laws for the former suffices for the latter. In Section 6.4, we manually constructed merge on paths from merge on histories (i.e., without univalence), so here we will prove the merge laws manually as well. Even so, the contractibility of $\text{R}$ is an important ingredient.

In Section 6 we defined merge on paths as

$$\text{merge} : \{n1 n2 : \text{Nat}\} (h1 : \text{History 0 n1}) (h2 : \text{History 0 n2}) \Rightarrow (\text{doc} [] = \text{doc} h1) \Rightarrow (\text{doc} [] = \text{doc} h2) \Rightarrow \Sigma (n' : \text{Nat}). \Sigma (h' : \text{History 0 n'}).$$

Given a merge $\text{merge} p1 p2 = \text{mergeH} (\text{interpH} p1 []) (\text{interpH} p2 [])$.

The proof is essentially the same as in the previous subsection; the first step will again be to prove that this $\text{merge}$ is contractible.

In this patch theory, the merge laws are:

$$\text{reconcile} : \{n1 n2 : \text{Nat}\} (h : \text{History 0 n})$$

In that case, the type of merge specifies that $p1$, $p2$, $q1$, and $q2$ form a square, and by contractibility, all squares in $\text{R}$ commute.
The symmetric law follows from the symmetry of \( \text{mergeH} \). Assume a proof:

\[
\begin{align*}
\text{symmetricH} : & \{n \, n1 \, n2 : \text{Nat}\} \{h : \text{History} \, 0 \, n\} \\
& \quad \to \ (h1 : \text{History} \, 0 \, n1) \ (h2 : \text{History} \, 0 \, n2) \\
& \quad \to \ \{e1 : \text{Extension} \, h1 \, h\} \ \{e2 : \text{Extension} \, h2 \, h'\} \\
& \quad \to \ \text{mergeH} \, h1 \, h2 = (n, (h, (e1, e2))) \\
& \quad \to \ \text{mergeH} \, h2 \, h1 = (n, (h, (e2, e1)))
\end{align*}
\]

The first two components of the two merges are equal because the same is true of \( \text{mergeH} \); the last two components, a pair of paths, are swapped because they depend only on the last two components of the corresponding \( \text{mergeH} \)s, which \text{symmetricH} ensures are also swapped.
